Attributes of algorithms

Which characteristics mark a good algorithm?

- Correctness
  - Give a correct solution to the problem!
- Ease of understanding
  - Clarity and ease of handling
- Program maintenance
  - Fix errors
  - Extend the program to meet new requirements
- Efficiency
  - Time: How long does it take to solve the problem?
  - Space: How much memory is needed?

A choice of algorithms

It is possible to come up with a several different algorithms to solve one and the same problem

- Which one is the best?
  - Most efficient: Time *vs.* Space
  - Easiest to maintain
- How do we measure time efficiency?
  - Running time?
  - Number of executed operations?

Measuring Efficiency

- Need a metric to measure efficiency of algorithms
  - Running Time: How long does it take to solve the problem?
    - Depends on machine speed
  - Number of Operations: How many operations does the algorithm execute?
    - Better metric but a lot of work to count all operations
  - Number of Fundamental Operations: How many "fundamental operations" does the algorithm execute?
- Depending on size and type of input, we are interested in:
  - Best-case, Worst-case, Average-case behavior
- Need to analyze the algorithm!

Example: Average of *n* numbers – counting

Problem: Find the average of *n* numbers

```
1  list_A = eval(input())
2  n = len(list_A)
3  sum = 0
4  i = 0
5  while i < n:
6      sum = (sum + list_A[i])
7      i = (i + 1)
8  average = sum/n
9  print(average)
```

- How many steps does the algorithm execute?
  - Steps 1, 2, 3,4, 8, and 9 are executed once.
  - Steps 5, 6, and 7 depend on the input size *n*.

Example: Average of n numbers – doing the sum

Problem: Find the average of n numbers

```
1  list_A = eval(input())  1 operation => executed once
2  n = len(list_A)         1 operation => executed once
3  sum = 0                 1 operation => executed once
4  i = 0                   1 operation => executed once
5  while i < n:            1 operation => (n+1) repetitions
6    sum = sum + list_A[i] 1 operation => n repetitions
7    i = i + 1             1 operation => n repetitions
8  average = sum/n         1 operation => executed once
9  print(average)          1 operation => executed once
```

Total number of executed operations

$$1+1+1+1+(n+1)+n+n+1+1 = 3n+7$$

Sequential search – Analysis

```
1  Name = eval(input())
2  list_N = eval(input())
3  list_T = eval(input())
4  n = len(list_N)
5  i = 0
6  Found = False
7  while Found == False and i < n:
8      if Name == list_N[i]:
9          print(list_T[i])
10         Found = True
11     else:
12         i = i + 1
13 if Found == False:
14     print("sorry, name is not in directory")
```

How many steps does the algorithm execute?

Sequential search – Analysis

How many steps does the algorithm execute?

- Steps 1, 2, 3, 4, 5, 6, 9, 10, 13 and 14 are executed at most once.
- Step 7 is executed at most $n + 1$ times.
- Steps 8 and 12 are executed at most n times.

So what is the running time now? (focus on the loop)

- Worst case: Steps 8 and 12 are executed at most n times and step 7 $n + 1$ times.
- Best case: Step 7 is executed exactly twice. Step 8 is executed only once.
- Average case: Steps 8 and 12 are executed approximately $\frac{n}{2}$ times.

Sequential search – Worst case behavior

```
1  Name = eval(input())                          1 ops => executed once
2  list_N = eval(input())                        1 ops => executed once
3  list_T = eval(input())                        1 ops => executed once
4  n = len(list_N)                               1 ops => executed once
5  i = 0;  Found = False                         2 ops => executed once
6  while (i < n and Found == False):             1 op => (n+1) reps
7   if Name == list_N[i]:                        1 op => n repetitions
8      print(list_T[i])                          skipped...
9      Found == True                             skipped...
10  else: i = i + 1                              1 op => n reps
11 if Found == False:                            1 op => executed once
12  print("Sorry, name not in directory")        1 op => executed once
```

Assume the name is not in the list!

Total number of executed operations

$$1 + 1 + 1 + 1 + 2 + (n + 1) + n + n + 1 + 1 = 3n + 9$$

Sequential search – Worst case behavior

```
1  Name = eval(input())                          1 ops => executed once
2  list_N = eval(input())                        1 ops => executed once
3  list_T = eval(input())                        1 ops => executed once
4  n = len(list_N)                               1 op => executed once
5  i = 0; Found = False                          2 ops => executed once
6  while (i < n and Found == False)              1 op => (n+1) reps
7    if Name = list_N[i]:                        1 op => n repetitions
8        print(list_T[i])                        1 op => executed once
9        Found = YES                             1 op => executed once
10   else: i = i + 1                             1 op => (n-1) reps
11 if Found == False:                            1 op => executed once
12   print("Sorry, name not in directory")       skipped...
```

Assume the name is the last one in the list!

Total number of executed operations

$1 + 1 + 1 + 1 + 2 + (n+1) + n + 1 + 1 + (n-1) + 1 \quad 2n + 9$

What really matters

- We are
  - not interested in knowing the exact number of operations the algorithm performs.
  - mainly interested in knowing how the number of operations grows with increased input size!
- Why?
  - Given large enough input, the algorithm with faster growth will execute more operations.

Consider algorithms A and B with input size $n = 10,000$:

- Algorithm A has a running time of $570n + 920$ operations $\rightarrow$ 5,700,920 operations.
- Algorithm B has a running time of $n^2 + 21$ operations $\rightarrow$ 100,000,021 operations.
- Algorithm B takes already twenty times longer!

The "Order of Magnitude"

The Order of Magnitude is a formula that strips away all ballast. For example...

- n
- $6n$
- $6n + 278$
- $5000n + 2000$

Are all in the Order of Magnitude of n

- n^3
- $200n^3 + 150n + 20$
- $50n^3 + n^2$

Are all in the Order of Magnitude of n^3

The “Big O notation”

- We write $O(n)$ for the Order of Magnitude of n.
- Generally, if a function g is in the Order of Magnitude of a function f, we write $(g = O(f))$.

For your reference...

Formally, the Order of Magnitude is defined as:

$$\exists c.\ \exists n_0.\ \forall n > n_0.\ c \cdot f(n) > g(n) \Leftrightarrow g = O(f)$$

You are only interested into the fastest growing part of the function you have!

Beware of fast growth!

Imagine algorithms A, B, and C, with

- A in $O(n)$,
- B in $O(n^2)$, and
- C in $O(2^n)$

Consider an operation taking $\frac{1}{100}$s

n	10	20	30	40
A	$\frac{1}{10}$s	$\frac{2}{10}$s	$\frac{3}{10}$s	$\frac{4}{10}$s
B	1s	4s	9s	16s
C	ca. 10s	ca. 3h	ca. 4 months	ca. 348 years

Some terms

- Algorithms in $O(1)$ are called constant
- Algorithms in $O(n)$ are called linear
- Generally, algorithms in $O(n^x)$ for some x are called polynomial (constant, linear, quadratic, cubic, ...)
- Algorithms in $O(2^n)$ are called exponential

Summary

- We are concerned about the efficiency of algorithms
  - Time and space efficiency
  - An analysis of the algorithm is necessary
- The order of magnitude (Big O notation) measures efficiency
  - $O(1)$, $O(n)$, $O(n^2)$, ...
  - Measures the growth with increasing input size n
  - Aim for low growth rates
