Abstract

The use of component models such as Enterprise Java Beans and the CORBA Component Model (CCM) in application development is expanding rapidly. Even in real-time safety/mission-critical domains, component-based development is beginning to take hold as a mechanism for incorporating non-functional aspects such as real-time, quality-of-service, and distribution. To form an effective basis for development of such systems, we believe that support for reasoning about correctness properties of component-based designs is essential.

In this paper, we present Cadena – an integrated environment for building and modeling CCM systems. Cadena provides facilities for defining component types using CCM IDL, specifying dependency information and transition system semantics for these types, assembling systems from CCM components, visualizing various dependence relationships between components, specifying and verifying correctness properties of models of CCM systems derived from CCM IDL, component assembly information, and Cadena specifications, and producing CORBA stubs and skeletons implemented in Java. We are applying Cadena to avionics applications built using Boeing's Bold Stroke framework.

1 Introduction

As software systems become more distributed, developers are increasingly turning to component-based development frameworks such as Java Enterprise Beans (EJB) and the CORBA Component Model (CCM) to manage the complexities associated with building distributed systems. These frameworks aid application developers by providing services for common aspects such as distributed deployment, event notification, transactions, persistence, and security. Moreover, they use accepted design patterns (e.g., the event-oriented observer pattern) which enables a significant amount of code to be auto-generated. Component-based frameworks are also attractive because the relatively loose coupling between components facilitates reuse and allows systems to evolve gracefully as old components are switched out for new ones.

Even in the domain of distributed real-time embedded (DRE) systems where hard/soft deadlines and minimal footprint requirements traditionally have led developers to eschew sophisticated middleware solutions, component-based infrastructures are growing more popular because hardware advances allow real-time and embedded requirements to be more easily achieved. In addition, component-based infrastructures provide a framework for systematically introducing important domain aspects such time-triggered notification, real-time scheduling, and fault tolerance.

There is a wide body of literature dealing with the theory of modeling distributed systems and automated analysis of high-level state-based models using state-space exploration techniques such as model-checking. However, despite the popularity of component-based frameworks and their potential to be utilized in mission- and safety-critical applications, relatively little has been done to scale up these analysis techniques for the purpose of providing automated analysis tools for component frameworks. This is particularly the case with CCM – partly due to the fact that the CCM specification as part of CORBA 3.0 has only recently been finalized. Popular tools such as Rational Rose do not even provide design support for CCM yet.

To investigate the effectiveness of a variety of behavioral analysis techniques for component-based systems, we have built Cadena\(^1\) – an integrated development environment for high-assurance CCM-based systems. The primary technical contributions of this paper are

- a framework for light-weight dependency analysis (with varying levels of precision) of component-based specifications, and
- a framework for extracting checkable transition system models from component-based specifications of sys-

\(^1\)“Cadena” is a Spanish word meaning “network”. Cadena is also an acronym for Component Architecture Development ENvironment for Avionics systems.

\(\star\) This work was supported in part by DARPA/IXO’s PCES program through AFRL Contract F33615-00-C-3044, by the U.S. Army Research Laboratory and the U.S. Army Research Office under agreement DAAD190110564, by Intel Corporation under grant 11462, and was performed for the Formal Verification of Integrated Modular Avionics Software Cooperative Agreement, NCC-1-399, sponsored by Honeywell Technology Center and NASA Langley Research Center.
tems that use middleware services (such as event services) where extracted models incorporate the threading semantics of the relevant middleware services.

These particular capabilities were developed in response to requests from Boeing engineers working on Boeing’s Bold Stroke avionics middleware infrastructure.

Boeing’s Bold Stroke program is an example where CORBA middleware has been embraced in a DRE domain for the reasons outlined above [20, 21, 9]. Bold Stroke is a product-line based program providing object-oriented mission critical avionics software to a variety of military aircraft produced by the Boeing company. Avionics software acts as the center of mission control for an aircraft pilot. It manages the cockpit displays, navigation and tactical sensors as well as weapon deployments. These complex systems have hard and soft real-time deadlines involving large amounts of periodic and aperiodic processing, and support thousands of operating modes. In addition, the software developed for military aircraft is maintained and updated over the course of many years. Although the development process is repeated for each update, each update aims to preserve as much legacy software as possible to reduce cost and risk. Bold Stroke represents a significant technological advance over Boeing’s previous mission computing development practices which were largely assembly code based.

During the past year, we have been interacting extensively with Bold Stroke engineers who have proposed a variety of interesting challenge problems related to component-based design and analysis. Work on Cadena is driven in large part by a desire to provide solutions to challenge problems related to behavioral analysis. Bold Stroke was initiated before the OMG CCM specification process was underway. Thus, the Bold Stroke component design, is slightly different from CCM, and therefore does not apply the CCM Interface Definition Language (IDL) (now part of OMG CORBA IDL 3.0) to auto-generate component code. In current practice, component developers receive a natural language description of functional and real-time requirements along with UML collaboration diagrams built with Rose showing component interactions, and development begins directly with C++ coding. This means that high-level designs are not tool-leveraged in any way (either for code generation or for automated analysis). Bold Stroke engineers have suggested a number interesting ways that high-level designs could be analyzed for event/data dependency and mode state information for the purpose of inferring distribution, scheduling, and real-time aspects, as well as checking for common design flaws and satisfaction of application specific requirements.

Beyond the particular domain of DRE mission/safety-critical systems, we believe that CCM and other component oriented frameworks are excellent vehicles for injecting light-weight formal methods and sophisticated automated analysis techniques across the entire software development process. In the past, it has often been difficult to get developers to write formal specifications — instead they prefer to move quickly to writing code. We believe that this is because there is little tool support for leveraging such high-level descriptions. In contrast, CCM’s IDL (which defines the structure of components) and CCM’s component assembly descriptions (which describe how components are connected together) are central to the use of CCM since a large percentage of a system’s code is generated directly from these. These high-level descriptions can be leveraged in a number of ways: component connections can be visualized (essentially, UML collaboration diagrams can be autogenerated), useful dependency analysis can be performed at this level, light-weight behavior specifications can be incorporated, and code generation can be tailored to produce code that is more amenable to verification and certification. When applying model-checking techniques, one often struggles to find appropriate system abstraction that make state exploration tractable. CCM descriptions naturally form system abstractions, and by varying annotations on the high-level descriptions (e.g., to expose the state of mode variables, etc.) the system model processed by model-checking techniques can be easily abstracted (to hide state) or refined (to expose more state and more interesting behaviors).

Cadena provides the following capabilities for development of CCM systems.

- A collection of light-weight specification forms that can be attached to IDL to specify mode variable domains, intra-component dependencies, and component state-transition semantics. These forms have a natural refinement order so that useful feedback can be obtained with little annotation effort, and increasing the precision of annotation yields more precise analysis. In addition, Cadena specifications allow developers to specify the same information in different ways, achieving a form of checkable redundancy that is useful for exposing design flaws.
- Dependency analysis capabilities allow tracing inter/intra-component event and data dependencies, as well as algorithms for synthesizing dependency-based real-time and distribution aspect information.
- A novel model-checking infrastructure dedicated to event-based inter-component communication via real-time middleware enables system design models (derived from CCM IDL, component-assembly descriptions and annotations) to be model-checked for global system properties.
- Java component stub and skeleton code generated using the OpenCCM [12] CCM IDL to Java compiler.
- A component assembly framework supporting a variety of visualization and programming tools for developing component connections.
- A CCM deployment facility dedicated to the Boeing Bold Stroke architecture (static component connections with a real-time event-channel) that allows deployment code to be automatically generated.
- The Cadena tools are implemented as plug-ins to IBM’s Eclipse IDE. This provides an end-to-end integrated development environment for CCM-based Java systems.
Several of these facilities are targeted directly to the avionics domain, but Cadena is useful in many respects for CCM development in general. Although Cadena currently emphasizes Java in its back-end facilities, since CCM is language-neutral, Cadena’s front-end design capabilities are not Java dependent. Moreover, back-end capabilities can be easily extended in the future to other languages, for example, C++ using OpenCCM’s [12] planned support for C++. Other development systems such as MetaH [24] support several important aspects for DRE systems that Cadena does not, such as timing and schedulability analysis, reliability and fault analysis, as well as sophisticated deployment strategies. The primary motivation for our work is to build a system that is robust enough for development of real systems with the goal of assessing the effectiveness of applying static analysis, model-checking, and other light-weight formal methods to CCM-based systems.

The rest of this paper is organized as follows. Section 2 gives a brief overview of CCM and the Bold Stroke architecture, and presents an example that will drive the discussion in the rest of the paper. Section 3 outlines the Cadena architecture and illustrates the various Cadena specification forms. Section 4 presents Cadena’s dependency analysis facilities. Section 5 describes Cadena’s model-checking facilities. Section 6 discusses related work. Section 7 assesses the current state of the tools and presents directions for future work.

2 CCM Overview and Example

To describe the features of Cadena, we will use as a running example a simple avionics system that shows steering cues on a pilot’s navigational display. The pilot can choose between two different display modes — each mode yields a different set of steering cues. A tactical display mode displays cues related to a tactical (i.e., mission) objective. A navigation display mode displays cues related to a navigational objective. Cues for the navigation display are derived in part from navigation steering points data that can be entered by the navigator.

Figure 1 presents the CCM architecture for the example system. The system is realized as a collection of components coupled together via interface and event connections. The system include three modal components (AirFrame, NavSteering, and TacticalSteering) whose behavior changes depending on the mode of the component (the mode of each component will be represented by an attribute with an appropriate enumeration type). Moreover, the system is designed to run on a single processor. For this reason, we refer to the example as ModalSP. Input position data is gathered periodically at a rate of 20 Hz in the GPS component and then passed to an intermediate AirFrame component (which in a more realistic system would take position data from a variety of other sensors). Both the NavSteering and TacticalSteering component produce cue data for Display based on air frame position data. The Navigator component polls for inputs from the plane navigator at a rate of 5 Hz and uses those to form NavSteeringPoints data. This data is then used to form navigational steering cues in NavSteering. PilotControl polls for a pilot steering mode at a rate of 1 Hz and enables or disables NavSteering and TacticalSteering accordingly.

Figure 2 gives the CCM IDL that defines the component types LazyActive and Modal1 for the AirFrame and TacticalSteering component instances in Figure 1. CCM components provide interfaces to clients on ports referred to as facets, and use interfaces provided by other clients on ports referred to as receptacles. Components publish events on ports referred to as event sources, and consume events on ports referred to as event sinks. In the LazyActive component type of Figure 2, dataOut is the name of a facet with interface type ReadData, and dataIn is the name of a receptacle with interface type ReadData. Similarly, inDataAvailable is the name of an event sink of type DataAvailable, and outDataAvailable is the name of an event source of type DataAvailable. Components can also have attributes such as modeVar that are used either in component configuration or to represent some other aspect of component state. For an attribute with name attrname, the IDL compiler will automatically generate an accessor method get_attrname and a mutator method set_attrname. If the attribute is declared readonly as in the ReadData interface of Figure 2, then only an accessor method is generated.

While CCM allows components to be dynamically created and (dis)connected, Bold Stroke applications follow typical practice in safety/mission-critical systems and employ

---

Footnote: 2 The name of the accessor/mutator methods is dependent on the IDL to language mapping.
Figure 1. ModalSP – a simple avionics system

Figure 3. Cadena Assembly Description for ModalSP (excerpts)
GPS data, sets its dataStatus to fresh, and returns the new AirFrame data to the calling client.

Both NavSteering and TacticalSteering are modal components that have two modes (enabled, disabled). These modes are set by PilotControl via ChangeMode facets provided by the modal components. When a component is disabled, any events received are simply discarded by the component. When enabled, the component responds according to the control-push data-pull strategy (e.g., TacticalSteering responds to a DataAvailable from AirFrame by calling AirFrame’s get data method.

In Bold Stroke applications, even though at a conceptual level component event source ports are connected to event sink ports, in the implementation, event communication is factored through a real-time CORBA event channel. Use of such infrastructure is central to Bold Stroke computation because it provides not only a mechanism for communicating events, but also a pool-based threading model, time-triggered periodic events, and event correlation. In order to shield application components from the physical aspects of the system, for product-line flexibility, and for run-time efficiency, all components are passive – component methods are run by event-channel threads that dispatch events by calling the event handlers (“push methods” in CORBA terminology) associated with event sink ports. The roots of computation are time-triggered events (e.g., events associated with event sinks of Navigator, GPS, and PilotControl) supplied at a specified rates by the event-channel. Dispatching of these events causes the dispatch threads to run the associated handlers which contain methods calls and publishing of subsequent events. In the current Bold Stroke implementation, the event channel thread pool has exactly one thread associated with each rate. As noted earlier in the discussion of Figure 3, each non-time-triggered event port also has a rate specified at configuration time which indicates its rate group, i.e., the pool thread that should run the event handler when the event is dispatched.

The event channel also provides event correlation and event filtering mechanisms. In the example system, and-correlation is used, for instance, to combine event flows from NavSteering and AirFrame into NavDisplay. The semantics of and-correlation on two events e1 and e2 is that the event channel waits for an instance of both e1 and e2 to be published before creating a notification event that is dispatched to the consumer of the correlation. The semantics of a correlator is defined by an automaton over event traces derived from the correlation expression [22].

Note that CCM IDL captures the interface properties of components – Cadena’s notation for expressing component behavior is presented in the next section.

3 Cadena Architecture

Figure 4 displays the internal structure of the Cadena toolset. Cadena projects contain four high-level specification forms: a CORBA 3 IDL file that defines the structure of component types (see Figure 2), a Cadena Property Specification (CPS) file that specifies various aspects of component behavior (see Figure 5), a Cadena Assembly Description (CAD) that specifies the components instances that form the system, the connections between them, along with other real-time and distribution property information (see Figure 3), and a specification file that stores information about the desired correctness properties of the system. These input artifacts are created using customized editors built using Eclipse plug-in facilities. In particular, the CAD format has a textual editor, a graphical editor (to view systems as graphs similar to style of Figure 1), and a form-based editor that allows one to easily define different projections of the component assembly (e.g., connections only, distribution and rate assignments only, etc.). The graph structure described by the CAD is the basic data structure that is used by the dependency analyzer (discussed in Section 4), the graphical view displayer, and the deployment code generator (which generates Java code to allocate and connect components).

Dependence Specifications: Figure 5 displays excerpts of the CPS file for our example system. In a CPS description, developers may declare intracomponent dependencies between ports and simple behavioral descriptions of a component’s event handlers and other methods. The dependence declarations take the form trigger-port-action -> response-port-action. For example, Figure 5 declares that consumption of an event on the inDataAvailable port of a LazyActive component may trigger a publish on the outDataAvailable port in both stale and fresh modes. The absence of a dependence for the dataOut port in the fresh mode indicates that any call on dataOut should not result in an action on any other port.

A dependency default may have one of two settings: a none setting allows developers to start with an empty dependence relation and add new dependencies (i.e., dependencies do not exist except when declared), an all setting allows developers to start with a universal dependence relation and then prune dependences (i.e., by default all possible dependencies between ports exist). In the all setting, once a port is mentioned on the left-hand-side, then only declared dependences apply for that port. For example, for Modal1 which has the all setting, the absence of declarations for the dataOut port specifies that the ports(outDataAvailable and dataIn) do depend on dataOut (note that is an overapproximation of the actual behavior). Dependencies are pruned in Modal1 by giving refining declarations such as those for the modeChange and inDataAvailable ports that list no dependents to the right of the ->.

Behavioral Specifications: Since transition systems for model-checking are generated from behavioral descriptions, their primary purpose is to capture (a) the actions that one wishes to reason about in temporal specifications and (b) simple control-flow relationships between these actions. Cadena supports observable actions such as event publish and consume, method call and return, data flows

    }
    behavior { ... }
}

Figure 5. Cadena Property Specification (CPS) (excerpts)

between system variables, assignments to mode variables. Each behavioral description in the CPS format gives both a data and control abstraction of a component’s actual implementation of an event handler or method. Data abstraction is achieved by only exposing concrete values of mode variables (or other application variables with bounded domains). This was motivated by the fact that Bold Stroke engineers are primarily concerned with reasoning about modal behavior at design time since analysis of system modes and mode transitions can be leveraged in several ways. Even though concrete values of other application variables are usually not modeled, data flows between such variables can be captured. For example, internalData <- dataIn.get_data(); in the LazyActive behavior models a flow from the result of the get_data(); method into the internalData variable. This may abstract many actual computation steps in the actual implementation. The behavioral language contains simple control structures such as sequencing and conditionals and abstracts control by simply omitting commands from the implementation that one does not wish to observe. Note that dependence information can also be derived from behavioral specifications, and this provides a form of checkable redundancy. The intent is that developers begin with the more light-weight dependence specifications, leverage those, then only incorporate behavioral specifications when model-checking analysis is to be applied.

Code Generation: Cadena uses the OpenCCM tools [12] to generate system implementations. The OMG CORBA 3.0 specification standardizes a strategy for compiling IDL (of which the CCM IDL is part) down to CORBA IDL 2, which can then be translated to an underlying implementation language such as Java or C++. This translation process automatically generates a substantial amount of infrastructure code for tasks such as component creation and connecting and disconnecting ports. The output code contains the usual CORBA stubs and skeletons, along with skeleton implementations of component methods and event handlers. With this code generation, the developer only needs to im-

Figure 4. Cadena architecture
placed event handlers and methods on provided interfaces. In future work we are exploring the extension of CCM-based code generation strategies to integrate code generation for component handler state-machines and global synchronization policies [8].

Methodology: When building systems with Cadena, we intend for developers to take the following steps: (1) load a library of domain-specific components and associated CPS specifications, (2) define new project-specific components and associated behavioral CPS specifications, (3) use CAD editors to configure connections between components, (4) use dependency viewer to examine dependencies, (5) use non-functional aspect synthesis tools to attach distribution and rate information (see Section 4.3), (6) specify desired global correctness properties (see Section 5.5), (7) generate a transition system model and model-check correctness properties (see Section 5), and (8) revise system based on feedback from analysis tools.

4 Dependency Analysis

Even with small systems of around 20-30 components, relationships between components and component dependences are often hard to determine from visual inspections of textual or graphical component assembly views. Bold Stroke systems can have 1000s of components, and Bold Stroke engineers have identified development of automated support for component dependency analysis and visualization as a high priority. As discussed in the previous section, Cadena provides several different layers of dependency specification and analysis with the goal of enabling incremental construction of dependency specifications—little or no specification effort should still allow useful tool feedback since a fair amount of dependency information (inter-component dependences) can be derived from the CAD information. Increasing the details of specifications should yield more precise visualizations and analysis. Here are the steps that we expect developers to take when creating and refining dependence information: (1) give component assembly without CPS dependence information using the global dependence default that all actions on input ports of a component \( C \) give rise to actions on all output ports of \( C \), (2) refine by giving dependences without taking into account modal behavior, (3) refine by considering modes in CPS dependence declarations, and (4) refine by giving behavioral descriptions (which capture dependence information via control-flow properties). Bold Stroke developers currently use dependency information manually to determine non-functional aspects such as distribution, connection implementation (synchronous vs. non-synchronous calls), rate group assignment, etc. Cadena leverages partial dependence information to provide automated support for developers.

4.1 Basic notions of dependency

Given a component library and component assembly description (along with optional Cadena property specification file), Cadena’s port-level dependency module builds a port dependence graph \( PDG = (N, E) \) where each node \( n \in N \) is a component/port pair \( i.p \). Edges (i.e., dependences) between PDG nodes arise from two sources: inter-component dependences corresponding to port connections specified in component assembly descriptions and intra-component dependences captured by CPS declarations in component property specifications. Whether or not intra-component dependences are generated for a particular instance \( C \) depends on the default dependence setting for \( C \) as discussed previously. The default setting is given by the global default dependence declaration unless a component-local default declaration exists.

For inter-component dependences, when there is a connection between \( i_1.p_1 \) and \( i_2.p_2 \) in the component assembly description, we say that \( i_1.p_1 \) is event dependent on \( i_2.p_2 \) (written \( i_2.p_2 \xrightarrow{\text{event}} i_1.p_1 \) — the arrow pointing in the direction of the event flow) if \( p_2 \) (resp. \( p_1 \)) is an event source (resp. sink). Similarly, with the above connection, \( i_1.p_1 \) is interface dependent on \( i_2.p_2 \) (written \( i_2.p_2 \xrightarrow{\text{interface}} i_1.p_1 \) ) when \( p_2 \) (resp. \( p_1 \)) is a facet (resp. receptacle). For example, from the CAD information in Figures 1 and 3, we have, e.g.,

\[
\text{GPS outDataAvailable} \xrightarrow{\text{AirFrame inDataAvailable}} \text{AirFrame dataOut}
\]

For intra-component dependences, for an instance \( i \) of component type \( c \), \( i.p_1 \) is trigger dependent on \( i.p_2 \) (written \( i.p_2 \xrightarrow{\text{trigger}} i.p_1 \) ) when either (1) \( p_2 \) is declared to trigger \( p_1 \) in the CPS for \( c \), or (2) the default dependency status for \( c \) is all and there exists no trigger declaration for \( p_2 \) in the Cadena specification for \( c \).

As with conventional work on dependences, a system slice for a particular point(s) of interest (referred to as the slicing criterion) is computed by taking the transitive closure of the PDG from the PDG node(s) corresponding to the slicing criterion. Basic slicing actions provided by Cadena include forward slice, backward slice, and slice intersections.

4.2 Mode-aware dependences

To reason about mode-aware dependences, the mode state of the system is captured formally via a mode-state vector \( m \) which holds values for one or more mode variables from the system being analyzed. In the ModalISP scenario, it is useful to consider a two-variable mode-state vector that holds the mode state of \( \text{NavSteering} \) and the mode state of \( \text{TacticalSteering} \). Given a PDG \( P = (N, E) \) for a system, a modal PDG \( P_m = (N_m, E_m) \) for mode-state vector \( m \) is formed by setting \( N_m = N \) and having \( E_m \) include all inter-component edges, but only intra-component edges that are enabled according to \( m \).

Cadena provides mechanisms for collecting a set of mode-state vectors and using these to drive visualization of dependences (i.e., Cadena users can choose to visualize dependences for a particular vector). Mode-state vector sets can be entered explicitly in a form-based view or generated automatically from the state-exploration techniques discussed in the following section. For instance, for the
mode-vector mentioned above, it is instructive to have a mode-based dependency view for the three mode-state vectors (disabled, disabled), (enabled, disabled), and (disabled, enabled).

4.3 Dependency-driven analyses

In the Bold Stroke development process, several non-functional system aspects that are currently designed manually can be aided or even synthesized automatically using the dependence analysis capabilities described above. These include (following the order in which they are carried out) assigning priorities/execution-rates to event consumer ports, appropriately distributing component instances to network nodes, and identifying opportunities for switching asynchronous remote event delivery (the default mechanism) to synchronous local method calls.

Rate Assignment: Automated rate assignment begins by assigning rates to each event consumer port that subscribes to a time-triggered event – the port simply is assigned the rate of the event. Using the results of the dependency analysis above, the process continues by propagating rate information along the PDG in a forwards direction and assigning the propagated rate value to each input and output port encountered. In cases where a port has more than one rate propagated to it (e.g., when event correlation is used, or when two different input ports influence an output port), the highest of the rates is propagated. The process continues until a fixpoint is reached and the resulting rates on event consumer ports bind CAD rate variables.

In the example in Figure 1, automated rate assignment would result in assigning 1Hz to the event consumer of PilotControl, and to the receptacles of PilotControl and the facets of TacticalSteering and NavSteering connected to PilotControl. Similarly, (a) all ports in Navigator, NavSteeringPoints are assigned 5Hz, and the two ports of NavSteering connected to NavSteering are assigned 5Hz, and (b) all ports in GPS and AirFrame are assigned 20Hz. There is now a conflict for the rates on the output ports of NavSteering due to the fact both 5Hz and 20Hz rates are flowing in, so the higher rate of 20Hz is used. The process continues until the remainder of the unassigned ports have a value of 20Hz.

Distribution Determination: The distribution algorithm then uses the rate information gathered above (a) to determine the traffic on the connections between components, and (b) to identify components to be deployed on a common location. In the example, the algorithm would group components closer to their trigger source with the traffic and rate information used as the arbitrating criteria.

In the example, Navigator and PilotControl would be assigned distinct locations, 1,1 and 1,2. The rest of the components would be assigned location 1,3 as the traffic between them is higher assuming all data and event types are of unit size. However, if the traffic on the data connection between Navigator and NavSteeringPoints was higher than the cumulative traffic on other connections on NavSteeringPoints then NavSteeringPoints would be assigned location 1,1. Although this simplistic example is not realistic, the ability to automatically leverage connection and rate information to provide developers with guidance about component distribution can be a significant advantage for large systems.

Synchronous Dispatch Optimization: For the reduction of asynchronous remote event deliveries, an event delivery between two component instance ports \(i_1, p_1\) and \(i_2, p_2\) that does not involve correlation can be reduced to a local method call when \(i_1\) and \(i_2\) are co-located and when the rates attached to \(p_1\) and \(p_2\) through the propagation above are the same. In the example, this optimization can be applied to all non-correlated event connections. However, if NavSteeringPoints and NavSteering were assigned different locations in the distribution step above, the optimization would not apply to that connection.

Finally, although we do not implement schedulability analysis in Cadena, we note that Cadena’s dependency specifications (in particular, mode-aware dependence information) can be used to improve static scheduling. Currently, static schedulability analysis in Bold Stroke is based on summing execution costs along call-tree paths deduced from component connections only (i.e., our all dependence mode with no declared dependences). Cadena specifications prune away many infeasible dependences, and therefore prune away infeasible paths that may cause worst-case execution time estimates to be more conservative than necessary. This can sometimes save a surprising amount of development time since systems are often restructured in significant ways to obtain schedulable computations.

5 Model-checking Designs

As illustrated in the previous section, light-weight dependence analyses can provide a wealth of information about relationships among design components. In addition to this, Cadena supports deeper semantic analysis of design behavior using model checking. Specifically, we support reasoning about logical properties of component-based designs expressed as assertions, invariants and sequencing properties over system states and actions, such as method calls and returns and event publications and consumptions.

In order to maximize the flexibility of Cadena in targeting different classes of component-based systems, we have designed a layered translation from our extended CCM-based specification languages to the input language of the DSpin [7] model checker. The translation includes modeling of: (i) component interfaces and behavior, (ii) the semantics of middleware components through which component execution is orchestrated, and (iii) event and data sources and sinks in the system environment. These translation aspects have well defined interfaces that make it easy to vary, for example, the semantics of middleware functions to suit a particular application domain. In the remainder of this section, we discuss each of these aspects in turn as well as our approach to specifying the properties to be checked.

Unlike much of the existing work in model checking system designs, we found it necessary to exploit knowledge of the
middleware and environment to achieve models that were compact enough to check in a reasonable amount of time. We describe how we abstracted domain knowledge for the Bold Stroke architecture to encode it into our models. We conclude with a discussion of our experiences model checking properties of several variations of models generated for the design from Figure 1.

5.1 Why DSpin?

Cadena uses DSpin as its model checking engine. In principle we could use any one of a number of available model checking tools, such as Spin [14] or NuSMV [2], however, component-based designs have a number of features that are difficult to express in the low-level input languages of such tools. For example, one needs to be able to define an object, i.e., a collection of data attributes, manipulate references to an object, and invoke the methods associated with an object. It is clearly possible to map such high-level constructs onto a model checker input language as JPF [13] and Bandera [4] do, but it is much easier when the model checker supports these constructs directly. DSpin is an extension to Spin that adds support for objects, functions, and references, among other features. DSpin is implemented in such a way that it runs as least as fast as Spin for the functionality they have in common [7] and our experience is that the performance penalty for using the extensions is minimal when compared to hand-optimized models.

5.2 Component Modeling

Translating Cadena components is straightforward. A component is implemented as a group of state variables, for attributes and modes, and DSpin function references, for the receptacle methods consumed from other components. Associated with each component is a group of functions that implement the event consumer methods (i.e., handlers) and methods provided by the component.

There are two advantages to this translation: it has a natural mapping back to the Cadena model which facilitates expressing diagnostic information about detected errors and it decouples the component from other components so that models can be easily reconfigured. For example, the `NavSteering` component, shown in Figure 6, does not encode the identity of `source1` from which it reads `dataIn1`. Rather, the component has a function reference that is assigned to the appropriate method reference based on configuration information. We have generated models with static configurations to date, but it is trivial to support dynamic reconfiguration.

5.3 Modeling Middleware Services

CCM systems assume the presence of middleware services such as an event-channel with a pool for dispatching threads to execute component code.

Modeling Event Services: In our DSpin models an event publication is achieved by sending the function reference for the component’s event handler and the identity of the event as a message to the process modeling the event-channel thread. That thread then invokes the event handler code for the component instance as illustrated in Figure 7, where `ftype` is a DSpin function reference and `mtype` is an enumeration encoding the events in the system.

It is easy to identify pairs of component instances where one publishes an event that is consumed by the second. Under certain constraints the behavior of those components may be sequenced, for example when they have the same rate assignments in a Bold Stroke application. Under these conditions, the generic function-event pair queuing mechanism described above may be replaced by direct calls from the component instance publishing the event to the handlers for component instances subscribed to that event. For example, all publications of `dataAvailable` events from the `NavSteering` component are made by calling the `Ref_NavSteering_update` function reference which is bound to the function in Figure 8. Sequencing execution...
of event publications and consumer code yields a smaller state space \(^4\) by reducing the data states associated with the thread queues, e.g., Rate1_queue.

Each event correlation in the system has its own DSpin function. This function is generated based on the automaton that defines the meaning of the correlation expression [22]. The correlation function acts as a handler for its input events, updates the state of the automaton, and when an accepting state is reached it publishes the correlated event to subscribers using the same mechanisms as described above. Since the correlation functionality is internal to the middleware service its internal steps are unobservable to the application, thus we model them as atomic transitions.

**Modeling Thread Services:** Middleware provides the threads on which application components execute, and it may also define a scheduling policy for those threads. When such a policy is available it can be exploited to reduce the state space of the generated model by eliminating interleavings of thread executions that violate the scheduling policy. Eliminating such interleavings also has the beneficial effect of improving the precision of analysis performed on the model.

**Bold Stroke applications use rate monotonic scheduling [16] for event-channel threads.** Rate monotonic scheduling is a pre-emptive priority based scheduling policy where higher rates are assigned higher priorities. Like most model checkers, DSpin does not support the definition of a specific scheduling policy, so we encode the policy directly in the DSpin model. This is achieved by guarding all component actions with a test that blocks the action if the component’s priority is less than the current runnable priority, which is stored in a global variable \(P\). The print statement of function Fun_NavSteering_switch_getData in Figure 6 illustrates such a guard. Guarded component actions are only enabled when the current runnable priority has been decremented to the component’s priority. A decrement is performed only when there are no enabled steps in the model which can be detected by the timeout predicate of Spin. Since this priority decrementing process must operate independent of component or event-channel thread execution it is modeled as the separate process shown in Figure 9.

The resulting model has several interesting properties.

\(^4\)A similar event-channel performance optimization is applied quite frequently in Bold Stroke applications.

---

**Figure 8. DSpin Model of intra-Rate-Group Push Proxy**

**Figure 9. Rate Selection Process**

It assures that the highest-priority runnable action will be performed; this yields a dramatic reduction in the system state space as discussed below. Note that components running at the highest system wide priority need not have their actions guarded. This, combined with the direct call modeling of event publication and handling, means that high-priority behavior effectively executes as a single atomic step in the model. The introduction of an explicit global priority does add a state variable to the system, but note that it only changes value when no other transitions in the model are enabled. Consequently, there are no possible interleavings of the different priority values with component/thread execution and the effect on the state space is trivial.

**5.4 Environment Modeling**

Cadena models capture the combined behavior of a collection of component instances working in concert to respond to external inputs and to produce appropriate outputs. We use the term environment to describe the entities that interact with the explicitly modeled system. Since Cadena models do not attempt to accurately model data values flowing between the environment and the system the only relevant inputs are environment initiated events. The semantics of those events and the pattern of event arrival at the system will vary with each application.

Our experience suggests that accurate modeling of environment initiated events is necessary both for precision in reasoning and for state space reduction. The Cadena tools have built-in support for generating environment models for Bold Stroke system designs. These systems are driven by periodic events generated by the middleware. The rates of these events are typically harmonic to enable reasoning about schedulability via rate monotonic analysis.

Our generated transition system models do not represent time explicitly, rather they constrain the number of timeout event publishes for a given rate relative to timeout publishes for its adjacent rates. For example, in the interval defined by a pair of 5 Hz timeout events there must be four 20 Hz timeouts. Constraining the timeout events appropriately is achieved by including a separate TLtimer process in the transition system that keeps track of an abstraction of time and triggers timeout events appropriately.

For a system with harmonic rates, one could simply keep a counter, \(t\), that is incremented from 0 up to the maximum rate, \(m\), by one to maintain an abstract time. For a 5 Hz rate
```c
proctype Timer () {
  int t = 0;
  do
    :: (t >= 6) -> t = 0
    :: (t < 6) ->
      if :: (t % 2) == 0 -> S_timeout15!1
        :: else
        fi;
      if :: (t % 3) == 0 -> S_timeout10!1
        :: else
        fi;
      if :: (t % 6) == 0 -> S_timeout5!1
        :: else
        fi;
    t = t + 1
  od;
}
```

Figure 10. Timeout Generation Process for 5, 10 and 15 Hz Rate Groups

Depending on the exact rates used in a system we can reduce the granularity of abstract time and achieve a state space reduction by reducing the number of values that t will take on. To do this we scale the LCM and each of the rates down by their greatest common factor (GCF) and adjust the modulo tests appropriately. For example, if the rates in a system are 5, 10 and 15, then the LCM is 30, the GCF is 5, and we increment t from 1 up to 6. The generated timer process for such a system is shown in Figure 10.

Rather than use the event publication mechanisms described in the previous section, for timeout events we use rendezvous channels to couple the timer and the processes that model rate-specific event channel threads (see Figure 7). The rate-specific processes force all processing of published events handled by components in that rate group to complete before executing the rendezvous with the timer. Figure 11 illustrates the possible behaviors that can arise in the generated transition system as a result of Timer’s behavior and the enforcement of rate monotonic scheduling. Processing in each rate group is forced to complete before the next timeout for that rate group. Processing in lower-priority rate groups can occur only after higher-priority processing has completed. No attempt is made in the transition system, however, to ensure that the amount of lower-priority processing that occurs is appropriate, either by restricting the amount that can occur (e.g., region A in Figure 11 performs an infeasibly large amount of work) or by forcing it to occur (e.g., the region between regions B and C in Figure 11 performs an infeasibly small amount of work).

5.5 Property Specification

We divide the problem of stating correctness properties of Cadena designs into two parts: defining observations of the behavior of the system that one wishes to make and defining patterns of observations that constitute correct system behavior. Our approach is similar to the one taken in the Bandera Specification Language [5].

In Cadena designs user’s may wish to reason about the call or return from a component method, the publication or consumption of an event, or the values of component modes. These basic observations can be qualified by component instance identity (e.g., a method call to a specific instance), parameter values (e.g., the return of a specific value from a method), component ports (e.g., the handling of an event on a specific component port), or rate groups (e.g., publishing an event from a specific rate group). The syntax for defining these observables mirrors the syntax of CCM and the Cadena extensions defined in this paper.

User’s can instantiate an existing set of property specification patterns [10] with Cadena observables to form specifications of desired system behavior. In addition, Cadena generates observable definitions in a format that is compatible with the Timeedit tool [23]. Timeedit supports graphical specification of properties that are made up of complex chains of observations. Figure 12 illustrates a Timeedit specification for the constrained response property: "when a 20 Hz timeout occurs and navigation steering mode is enabled, the display will be updated by the navigation component and not the tactical component".

5.6 Experience

We have model checked properties of several Cadena designs. The most interesting of these is the modal scenario of Figure 1.
As a point of comparison, we generated a DSpin model for this scenario that did not enforce the rate-monotonic scheduling policy and performed an exhaustive state-space exploration for the number of timeouts issued in a single second of system execution. We ran DSpin using the maximal state compression settings available (which are the same as Spin’s compression settings) and the check aborted after generating 26 million states using 1 Gigabyte of RAM. Clearly, some form of state space reduction was necessary. A state-space exploration on a model of the same design that encoded rate-monotonic scheduling for an arbitrary number of timeouts, ran in less than a minute and generated 1.4 million states using 130 Megabytes of RAM.

Similar state space sizes were found for all of our checks on the modal scenario.

We attempted to check several assertions, invariants and the display mode related response property shown in the previous section. The property from Figure 12 failed on the model with non-deterministic scheduling due to the fact that execution of a 20 Hz component was preempted by a 1 Hz component. Thus, the steering component mode settings could change after the 20 Hz timeout and before the display update occurred. This is clearly infeasible in the actual system and performing the check on the rate-monotonic model described above bore that out by verifying the property.

The modal scenario is unrealistic in the number of components, but it is quite realistic in the number of rate groups. Recall that high-priority component execution is effectively atomic in models that encode rate-monotonic scheduling. This suggests that the rate of growth of the state space with increasing numbers of high-priority components will be linear whereas increasing numbers of lower-priority will yield faster rates of growth. We are conducting experiments with a variety of Cadena designs of Bold Stroke applications and plan to report on the scalability of our approach.

6 Related Work

There has been a large body of work on on timing and schedulability analysis for component-based systems. As these techniques have matured, they have been integrated into environments that support the development of real-time systems. For example, MetaH [24] and Geodesic [6] are frameworks that support the reuse of components written in Ada and Java, respectively, in real-time systems. These frameworks include a range of timing analyses and automatically generate infrastructure code that coordinates the execution of component code in a way that achieves the system’s timing requirements. Cadena is complementary to this work in that it targets logical properties of a system using both light-weight and heavy-weight analysis techniques.

Ptolemy [18] is a framework that allows a wide variety of formal descriptions of components and their behavior to be integrated into a single system. User’s provide sufficient detail in these descriptions to allow implementations to be automatically generated. Ptolemy provides a run-time infrastructure to mediate between components that have different execution models. In contrast, Cadena models intentionally leave out detail in order to provide more abstract system descriptions that are amenable to analysis for large systems. While Cadena provides some code generation capabilities, we do attempt to generate component method implementations.

Dependence analysis has a long history of uses in program understanding, transformation, maintenance and testing (e.g., [15]). Our use of dependence analyses is essentially an adaptation of existing techniques to the level of abstraction present in CCM designs. Unlike most program dependence analyses which work from a fixed language definition, we have engineered the annotation languages in Cadena to provide a layering of detail that will allow for more precise dependences to be calculated and exploited for improved user feedback.

Model checking [3] has become extremely popular as a technology for analyzing behavioral models of software artifacts. Researchers have extracted such models from source code (e.g., [13, 4]), UML design artifacts (e.g., [19, 17]) and architectural descriptions (e.g., [1]). The difficulty with all applications of model checking is scaling it to apply to realistically large and complex systems. Recent years have seen an enormous amount of research on the systematic abstraction of models to enable more tractable reasoning. We take a different approach in Cadena by exploiting the natural abstractions that arise when developing high-level design models of systems.

Our model extraction techniques are based on our experiences with Bandera [4]. We have adapted those techniques to exploit knowledge of the execution environment of Bold Stroke applications. This can provide significant state space reduction, but, in support of broad applicability of Cadena to CCM-based systems it was important to engineer the model extraction framework to accommodate the semantics of different middleware infrastructures in the spirit of Garlan [11].

7 Conclusion

Component frameworks have proven to be effective in dealing with the challenges associated with building complex distributed systems. We believe that the high-level architectural descriptions used by CCM and other component oriented frameworks are an excellent vehicle for injecting light-weight formal methods and sophisticated automated analysis techniques across the entire software development process. In particular, we have built Cadena to explore how static analysis and model-checking can be integrated into CCM development by capitalizing on the use of CCM IDL to define what are, in effect, system abstractions that make such checking feasible for realistic systems.

We have applied Cadena to small and simple avionics systems based on the Boeing Bold Stroke architecture, and the initial results are encouraging. We believe that the strategies that we have developed for modeling middleware event services can scale reasonably well to larger systems. However, for systems with 1000s of components as one would find in product-line applications, we plan to
investigate the use of compositional checking. In addition, there are many other forms of analysis needed for developing product-line avionics applications; Cadena current focuses on dependence analysis and behavioral analysis using model-checking techniques.

Concerning the tool itself, we believe building Cadena as a plug-in to IBM’s Eclipse using the OpenCCM tools can provide a tool environment robust enough to experiment with designs of real systems. More information about the tool (with example artifacts and screen shots) can be found at www.cis.ksu.edu/santos/cadena.
